- Let us say we have a TFL shell which summarizes the result and change from baseline at each visit and ' in the screenshot below.

	Treatment 1			
	Result			
	n	Mean	SD	n
Baseline	xx	xx.x	xx.xx	xx
Week 2	xx	xx.x	xx.xx	xx
Week 4	xx	xx.x	xx.xx	xx
Week 8	xx	xx.x	xx.xx	xx
Week 24	xx	xx.x	xx.xx	xx
Maximum value postbaseline	xx	xx.x	xx.xx	xx

For the derived datasets to be analysis-ready, we need to identify the maximum value observed during postba how to organize the analysis dataset.

In ADaM implementation guide, there are certain rules that guide a user on when to add an analysis data poin 'Column'.

Rule 3

A function of one or more rows within the same parameter for the purpose of creating an analysis timepoint sl same parameter.

- 'Maximum value postbaseline' is considered as 'conceptual' analysis timepoints in the shell provided to u
- So, we need to apply 'Rule 3' for this scenario and add new rows for the same parameter in this scenario

In this lesson, we will see:

- How to identify the record with maximum value and append that record to parent dataset
- Usage of 'DTYPE' variable to identify the derived records.
