Baseline result

- In clinical trials, we often want to see how the treatment is affecting a particular test/parameter value
 - Example: How is the treatment impacting the systolic blood pressure value of a subject
- For this, we need to have something as reference - a result which is collected prior to administering any treatment, to compare with post treatment values
- The pre-treatment value is generally considered as 'baseline' result
- The post-treatment results are then compared with baseline result and this comparison is generally the difference between post-treatment value and baseline result
- This difference is called as 'change from baseline'
- Sometimes, the percentage change from baseline at post-treatment timepoint is also needed

ADaM implementation

- ADaM datasets support this baseline and change from baseline related analysis
- ABLFL variable is used to indicate the baseline result
- BASE variable is used to populate the baseline result of a parameter of that subject
- CHG variable is used to populate the change from baseline result
- PCHG variable is used to populate the percentage change from baseline result
